## 1 Introduction

The purpose of this library is to provide HDL implementations for common fixed-point signal processing components along with bittrue Python models. The Python models are also callable from MATLAB.

This document serves as description of the RTL implementation for all components.

# 1.1 Working Copy Structure

If you just want to use some components out of the *psi\_fix* library, the only requirement is to checkout *psi\_common* into the same directory as *psi\_fix* (side-by-side). The reason for this is that *psi\_fix* uses some components from the library *psi\_common*.

If you want to also run simulations and/or modify the library, additional repositories are required (available from the same source as *psi\_fix*) and they must be checked out into the folder structure shown in the figure below since the repositories reference each-other relatively.

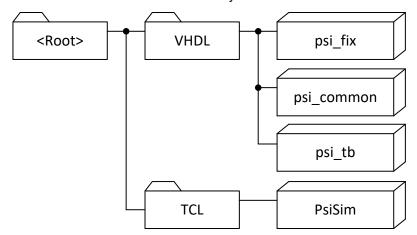

Figure 1: Working copy structure

It is not necessary but recommended to use the name *psi\_lib* as name for the *<Root>* folder.

# 1.2 External Dependencies

- Python 3.5 or higher is required to run the bit-true models of the psi\_fix library (which implicitly happens during regression tests)
- Python 3 must be callable using "python3" from the commandline on your system. For Linux this is the default, for windows it is recommended to create a copy of python.exe that is named python3.exe. Additionally the path to the python directory must be added to the PATH environment variable.
- The following packages from pip must be installed ("pip install <package>")
  - Scipy
  - o numpy

## 1.3 VHDL Libraries

The PSI VHDL libraries (including *psi\_fix*) require all files to be compiled into the same VHDL library.

There are two common ways of using VHDL libraries when using PSI VHDL libraries:

- a) All files of the project (including project specific sources and PSI VHDL library sources) are compiled into the same library that may have any name.
   In this case PSI library entities and packages are referenced by work.psi\_library>\_<xxx> (e.g. work.psi\_fix\_bin\_div or work.psi\_common\_array\_pkg.all).
- b) All code from PSI VHDL libraries is compiled into a separate VHDL library. It is recommended to use the name psi\_lib.
   In this case PSI library entities and packages are referenced by psi\_lib.psi\_lib.psi\_fix\_bin\_div or psi\_lib.psi\_common\_array\_pkg.all).

# 1.4 Running Simulations

Currently only Modelsim is is supported, support for GHDL is planned.

## 1.4.1 Regression Test

To run the regression test, follow the steps below:

- Open Modelsim
- The TCL console, navigate to <Root>/VHDL/psi\_fix/sim
- Execute the command "source ./run.tcl"

All test benches are executed automatically and at the end of the regression test, the result is reported. Note that python is called during that process, so if you python is not installed correctly, errors will occur.

# 1.4.2 Working Interactively

During work on library components, it is important to be able to control simulations interactively. To do so, it is suggested to follow the following flow:

- Open Modelsim
- The TCL console, navigate to <Root>/VHDL/psi\_fix/sim
- Execute the command "source ./interactive.tcl"
  - This will compile all files and initialize the PSI TCL framework
  - From this point on, all the commands from the PSI TCL framework are available, see documentation of PsiSim
- Most useful commands to recompile and simulate entities selectively are
  - compile\_files -contains <string>
  - o run\_tb -contains <string>

## 1.5 Contribute to PSI VHDL Libraries

To contribute to the PSI VHDL libraries, a few rules must be followed:

- Good Code Quality
  - There are not hard guidelines. However, your code shall be readable, understandable, correct and save. In other words: Only good code quality will be accepted.
- Configurability
  - If there are parameters that other users may have to modify at compile-time, provide generics.
     Only code that is written in a generic way and can easily be reused will be accepted.
- Bit-true model
  - A bit-true python model must be provided for psi\_fix components. Otherwise they will not be accepted.
- Self checking Test-benches
  - It is mandatory to provide a self-checking test-bench with your code.
  - The test-bench shall cover all features of your code
  - The test-bench shall automatically stop after it is completed (all processes halted, clockgeneration stopped). See existing test-benches provided with the library for examples.
  - o The test-bench shall only do reports of severity *error*, *failure* or even *fatal* if there is a real problem.
  - o If an error occurs, the message reported shall start with "###ERROR###:". This is required since the regression test script searches for this string in reports.
  - For *psi\_fix*, the test bench must call the python model and check if VHDL and python are bit-true

#### Documentation

- Extend this document with proper documentation of your code.
- New test-benches must be added to theregression test-script
  - Change /sim/config.tcl accordingly
  - Test if the regression test really runs the new test-bench and exits without errors before doing any merge requests.

# 1.6 Handshaking Signals

#### 1.6.1 General Information

The PSI library uses the AXI4-Stream handshaking protocol (herein after called AXI-S). Not all entities may implement all optional features of the AXI-S standard (e.g. backpressure may be omitted) but the features available are implemented according to AXI-S standard and follow these rules.

The full AXI-S specification can be downloaded from the ARM homepage: https://developer.arm.com/docs/ihi0051/a

The most important points of the specification are outlined below.

## 1.6.2 Excerpt of the AXI-S Standard

A data transfer takes place during a clock cycle where TVALID and TREADY (if available) are high. The order in which they are asserted does not play any role.

- A master is not permitted to wait until TREADY is asserted before asserting TVALID.
- Once TVALID is asserted it must remain asserted until the handshake occurs.
- A slave is permitted to wait for TVALID to be asserted before asserting the corresponding TREADY.
- If a slave asserts TREADY, it is permitted to de-assert TREADY before TVALID is asserted.

An example an AXI handshaking waveform is given below. All the points where data is actually transferred are marked with dashed lines.

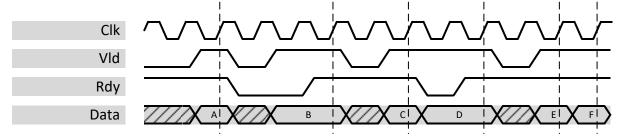

Figure 2: Handshaking signals

# **1.6.3 Naming**

The naming conventions of the AXI-S standard are not followed strictly. The most common synonyms that can be found within the PSI VHDL libraries are described below:

TDATA InData, OutData, Data, Sig, Signal, <application specific names>

TVALID VId, InVId, OutVId, Valid, str, str\_i

TREADY Rdy, InRdy, OutRdy

Note that instead of one TDATA signal (as specified by AXI-S) the PSI VHDL Library sometimes has multiple data signals that are all related to the same set of handshaking signals. This helps with readability since different data can is represented by different signals instead of just one large vector.

# 2 Tipps & Tricks

# 2.1 Library Setup

The *psi\_fix* library refers to *psi\_common* and *psi\_tb* relatively and assumes the contents of these repositories are compiled into the same VHDL library.

There are two common ways of setting up projects without toubles:

- 1. *psi\_fix, psi common* and *psi\_tb* are compiled into a VHDL library called *psi\_lib*. The project specific code is compiled to a different library and it refers to library elements using *psi\_lib.*<any\_entity>.
- 2. All code of the complete project including *psi\_fix*, *psi common* and *psi\_tb* is compiled into the same library. Independently of the name of that library, library elements can be referred to using *work.*<any\_entity>.

# 2.2 Heavy Pipelining

## 2.2.1 Problem Description

The following code may lead to suboptimal results for very high clock frequencies because there are three operations in the same pipeline stage:

- · The actual addition
- Rounding (adding of a rounding constant)
- Limitting

```
constant aFmt_c : PsiFixFmt_t := (1, 8, 8);
constant bFmt_c : PsiFixFmt_t := (1, 8, 8);
constant rFmt_c : PsiFixFmt_t := (1, 8, 0);
...

p : process(Clk)
begin
   if rising_edge(Clk) then
       r <= PsiFixAdd(a, aFmt_c, b, bFmt_c, rFmt_c, PsiFixRound, PsiFixSat);
   end if;
end process;</pre>
```

This leads to the implementation shown below.

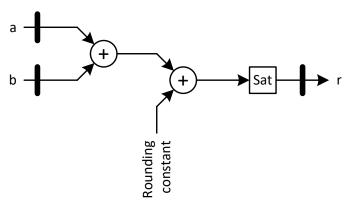

Figure 3: Heavy Pipelining, Problem Description

## 2.2.2 Solution 1: Register Retiming

Todays FPGA tools are quite good at register retiming. This means that the tools moves pipeline stages to optimize timing. ISE is also able to do retiming but it must be actively enabled in the project settings (synthesis).

Thanks to retiming, the user can just add a few pipeline stages at the output of the logic and the tool will move them into the logic to optimize timing.

```
constant aFmt_c : PsiFixFmt_t := (1, 8, 8);
constant bFmt_c : PsiFixFmt_t := (1, 8, 8);
constant rFmt_c : PsiFixFmt_t := (1, 8, 0);

...

p : process(Clk)
begin
   if rising_edge(Clk) then
       r1 <= PsiFixAdd(a, aFmt_c, b, bFmt_c, rFmt_c, PsiFixRound, PsiFixSat);
       r2 <= r1;
       r <= r2;
   end if;
end process;</pre>
```

The code above theoretically describes the following circuit which is not more timing-optimal than the original circuit:

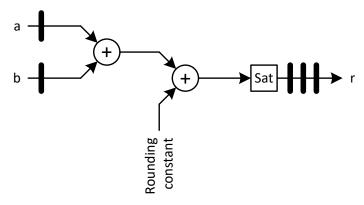

Figure 4: Heavy Pipelining, Retiming, Implementation without retiming

However, it register retiming is applied, the tool will convert the circuit into something as shown below. This is way more timing optimal and allows achieving higher clock frequencies.

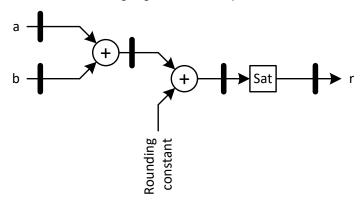

Figure 5: Heavy Pipelining, Retiming, Implementation with retiming

## PAUL SCHERRER INSTITUT

The advantage of the solution using retiming is, that the pipeline registers can be moved at a very finegrained level (even finer than one VHDL code line) and the tool is free to move the pipeline stages to the optimal place.

The drawback is that this approach relies on the tool to recognize the timing problem and fix it by applying retiming. If the tool fails to do this for whatever reason, the design will not meet timing.

## 2.2.3 Solution 2: Manual Splitting

The operation can be split into multiple stages manually on VHDL level. This can be done by not doing all steps in one VHDL line but one after the other in multiple lines. Of course intermediate number formats must be chosen accordingly to ensure correct operation. An example is given below.

```
constant aFmt c
                  : PsiFixFmt t := (1, 8, 8);
constant bFmt c : PsiFixFmt t := (1, 8, 8);
constant addFmt c : PsiFixFmt t := (1, 9, 8); -- + 1 Int-Bit for addition
constant rndFmt c : PsiFixfmt t := (1, 10, 8); -- + 1 Int-Bit for adding RC
constant rFmt c : PsiFixFmt t := (1, 8, 0);
p : process(Clk)
begin
   if rising edge(Clk) then
      -- addition only, no rounding or satturation
      add <= PsiFixAdd(a, aFmt c, b, b Fmt c, addFmt c, PsiFixTrunc, PsiFixWrap);
      -- rounding only
      rnd <= PsiFixResize(add, addFmt c, rndFmt c, PsiFixRound, PsiFixWrap);</pre>
      -- saturation ony
      r <= PsiFixResize(rnd, rndFmt c, rFmt c, PsiFixTrunc, PsiFixSat);</pre>
   end if;
end process;
```

This code directly leads to the implementation shown below and does not rely on the tools to do the retiming.

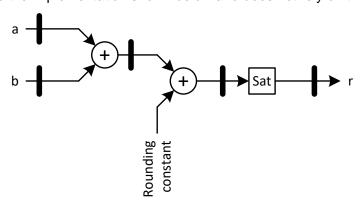

Figure 6: Heavy Pipelining, Manual Splitting

The advantage of this approach is that it does not rely on any tool-optimization.

The disadvantage is that slightly more code is required.

Or course the tools can still apply retiming to move the registers if required.

# 3 RTL Descriptions

# 3.1 psi\_fix\_bin\_div

## 3.1.1 Description

This component implements a fixed point binary divider.

$$Quotient = \frac{Nomerator}{Denominator}$$

### 3.1.2 Generics

NumFmt\_g Numerator format
DenomFmt\_g Denominator format
QuotFmt\_g Quotient format

**Round\_g** Rounding mode at the output (round or truncate) **Sat\_g** Saturation mode at the output (saturate of wrap)

### 3.1.3 Interfaces

Signal	Direction	Width	Description
Control Signals	5		
Clk	Input	1	Clock
Rst	Input	1	Reset
Input			
InVld	Input	1	AXI-S handshaking signal
InRdy	Output	1	AXI-S handshaking signal
InNum	Input	NumFmt_g	Numerator input
InDenom	Input	DenomFmt_g	Denominator input
Output			
OutVld	Output	1	AXI-S handshaking signal
OutQuot	Output	QuotFmt_g	Quotient output

At the input a handshaking for handling backpressure (incl. Rdy) is implemented since the binary divider is quite slow and may be the limiting component in offline data processing systems. At the output no handling for backpressure is implemented for simplicity reasons.

## 3.1.4 Architecture

The component converts numerator and denominator to unsigned numbers, so a standard binary divider can be implemented. At the output, the sign is restored correctly.

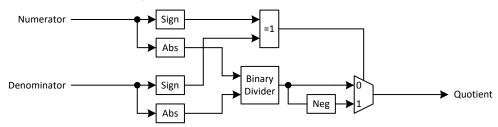

Figure 7: psi\_fix\_bin\_div Architecture

# 3.2 psi\_fix\_cic\_dec\_fix\_1ch

## 3.2.1 Description

This component implements a simple CIC decimator for a single channel. The decimation ratio must be known at compile time.

The CIC component always corrects the CIC gain roughly by shifting. As a result, the gain of the component is always between 0.5 and 1.0. Additionally a multiplier for exact gain adjustment can be added by setting the generic *AutoGainCorr\_g* to true. In this case the gain is corrected to exactly 1.0.

## 3.2.2 Generics

Order\_g Order of the CIC filter (number of integrator/comb pairs)

Ratio\_g Decimation ratio

**DiffDel\_g** Delay for the comb sections (1 or 2)

InFmt\_g Input format OutFmt\_g Output format

AutoGainCorr\_g True = compensate gain to 1.0, False = gain is between 0.5 and 1.0

#### 3.2.3 Interfaces

Signal	Direction	Width	Description		
Control Signals	Control Signals				
Clk	Input	1	Clock		
Rst	Input	1	Reset		
Input	Input				
InVld	Input	1	AXI-S handshaking signal		
InData	Input	InFmt_g	Filter input		
Output					
OutVld	Output	1	AXI-S handshaking signal		
OutData	Output	InFmt_g	Filter output		

The CIC is able to process one input sample per clock cycle. Therefore no backpressure handling is implemented on the input.

CIC are most commonly used in streaming signal processing systems that require processing or storing the data at the full speed anyway. So no backpressure handling is implemented on the output side for simplicity

#### 3.2.4 Architecture

The figure below shows the architecture of the CIC decimation filter.

Since the integrators are responsible for most of the CIC gain, the numbers are shifted and truncated after the integrator sections to the width required for producing less than 1 LSB error at the output. This allows saving some resources in the differentiator sections.

Note that the number format for the differentiator sections has one additional fractional bit (compared to the output format) per section. This results from the fact that depending on the signal frequency, the differentiators can have a gain up to two. This way the least significant bit at the input of the differentiators that can change the output by one LSB is preserved.

If the gain correction multiplier is used, signal path is chosen to be 25 bits wide and the gain correction coefficient is 17 bits (unsigned). For most implementations this design decisions are sufficient. If other requirements exist (e.g. very wide signal path), a project specific implementation of the CIC is required.

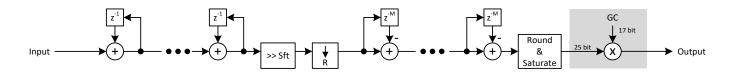

Figure 8: psi\_fix\_cic\_dec\_fix\_1ch Architecture

The symbols are defined as follows:

- R Decimation ratio
- M Differential delay
- N CIC order
- Sft Number of bits to shift (to compensate overall gain to 0.5 < gain < 1.0)
- GC Gain correction factor to compensate overall gain to 1.0

Some of the most common formulas are given below.

$$Gain_{CIC} = (R \cdot M)^N$$

$$Sft = ceil(log_2(Gain_{CIC}))$$

For the case that the gain correction amplifier is disabled, the overall gain of the CIC is:

$$GainOverallNoGc = \frac{Gain_{CIC}}{2^{Sft}}$$

Since this formula evaluates to 1.0 for the case  $R = x^2$  (decimation ratio is a power of two), the gain correction multiplier is not required in this case.

The optimal setting for the differential delay depends on the use case. Only the values 1 and 2 are supported. Other values are uncommon in real-life. Usually 1 is used if an FIR filter follows the CIC to further reduce the passband. If no FIR follows the CIC, a value 2 to is more optimal to avoid strong aliasing.

# 3.3 psi\_fix\_cic\_dec\_fix\_nch\_par\_tdm

## 3.3.1 Description

This component implements a decimating multi-channel CIC filter that takes all channels in parallel on the input side but delivers output in TDM fashion.

This filter is equal to the one described in 3.2, the only difference is that it supports multiple channels. So for details refer to 3.2.

## 3.3.2 Generics

**Channels\_g** Number of channels (must be >= 2)

Order\_g Order of the CIC filter (number of integrator/comb pairs)

Ratio\_g Decimation ratio

**DiffDel\_g** Delay for the comb sections (1 or 2)

InFmt\_g Input format OutFmt\_g Output format

AutoGainCorr\_g True = compensate gain to 1.0, False = gain is between 0.5 and 1.0

#### 3.3.3 Interfaces

Signal	Direction	Width	Description		
Control Signal	s				
Clk	Input	1	Clock		
Rst	Input	1	Reset		
Input					
InVld	Input	1	AXI-S handshaking signal		
InData	Input	InFmt_g*Channels_g	Input data in parallel - Channel 0 [N-1:0] - Channel 1 [2*N-1:0]		
Output	Output				
OutVld	Output	1	AXI-S handshaking signal		
OutData	Output	OutFmt_g	Output data in TDM fashion. The first output sample is Channel 0, then Channel 1,		

The CIC is able to process one input sample per clock cycle. Therefore no backpressure handling is implemented on the input.

CIC are most commonly used in streaming signal processing systems that require processing or storing the data at the full speed anyway. So no backpressure handling is implemented on the output side for simplicity

## 3.3.4 Architecture

For details on the filter mathematics, refer to 3.2.4. This section only describes how the multi channel filter is implemented.

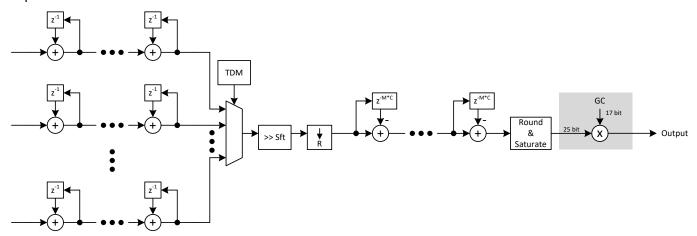

Figure 9: psi\_fix\_cic\_dec\_fix\_nch\_par\_tdm Architecture

The symbols are defined as follows:

- R Decimation ratio
- M Differential delay
- N CIC order
- C Number of channels
- Sft Number of bits to shift (to compensate overall gain to 0.5 < gain < 1.0)
- GC Gain correction factor to compensate overall gain to 1.0

# 3.4 psi\_fix\_cic\_dec\_fix\_nch\_tdm\_tdm

## 3.4.1 Description

This component implements a decimating multi-channel CIC filter that works in TDM fashion.

This filter is equal to the one described in 3.2, the only difference is that it supports multiple channels. So for details refer to 3.2.

### 3.4.2 Generics

**Channels\_g** Number of channels (must be >= 2)

Order of the CIC filter (number of integrator/comb pairs)

Ratio\_g Decimation ratio

**DiffDel\_g** Delay for the comb sections (1 or 2)

InFmt\_g Input format OutFmt\_g Output format

AutoGainCorr\_g True = compensate gain to 1.0, False = gain is between 0.5 and 1.0

#### 3.4.3 Interfaces

Signal	Direction	Width	Description	
Control Signal	ls			
Clk	Input	1	Clock	
Rst	Input	1	Reset	
Input				
InVld	Input	1	AXI-S handshaking signal	
InData	Input	InFmt_g	Input data in parallel. The first sample is Channel 0, the second one Channel 1,	
Output				
OutVld	Output	1	AXI-S handshaking signal	
OutData	Output	OutFmt_g	Output data in TDM fashion. The first output sample is Channel 0, then Channel 1,	

The CIC is able to process one input sample per clock cycle. Therefore no backpressure handling is implemented on the input.

CIC are most commonly used in streaming signal processing systems that require processing or storing the data at the full speed anyway. So no backpressure handling is implemented on the output side for simplicity

## 3.4.4 Architecture

For details on the filter mathematics, refer to 3.2.4. This section only describes how the multi channel filter is implemented.

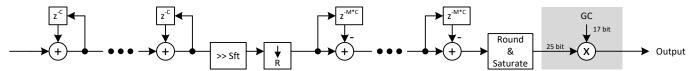

Figure 10: psi\_fix\_cic\_dec\_fix\_nch\_tdm\_tdm Architecture

The symbols are defined as follows:

- R Decimation ratio
- M Differential delay
- N CIC order
- C Number of channels
- Sft Number of bits to shift (to compensate overall gain to 0.5 < gain < 1.0)
- GC Gain correction factor to compensate overall gain to 1.0

# 3.5 psi\_fix\_cic\_int\_fix\_1ch

## 3.5.1 Description

This component implements a simple CIC interpolator for a single channel. The interpolation ratio must be known at compile time.

The CIC component always corrects the CIC gain roughly by shifting. As a result, the gain of the component is always between 0.5 and 1.0. Additionally a multiplier for exact gain adjustment can be added by setting the generic *AutoGainCorr\_g* to true. In this case the gain is corrected to exactly 1.0.

## 3.5.2 Generics

Order\_g Order of the CIC filter (number of integrator/comb pairs)

Ratio\_g Interpolation ratio

**DiffDel\_g** Delay for the comb sections (1 or 2)

InFmt\_g Input format OutFmt\_g Output format

AutoGainCorr\_g True = compensate gain to 1.0, False = gain is between 0.5 and 1.0

## 3.5.3 Interfaces

Signal	Direction	Width	Description	
Control Signals	5			
Clk	Input	1	Clock	
Rst	Input	1	Reset	
Input	Input			
InVld	Input	1	AXI-S handshaking signal	
InRdy	Output	1	AXI-S handshaking signal	
InData	Input	InFmt_g	Denominator input	
Output	Output			
OutVld	Output	1	AXI-S handshaking signal	
OutRdy	Input	1	AXI-S handshaking signal	
OutData	Output	InFmt_g	Quotient output	

The CIC interpolator requires full handshaking including the handling of back-pressure at the input since it can only take one sample every N clock cycles. As a result, the *InRdy* signal is required to signal when an input sample was processed.

Full handshaking at the output side was implemented mainly to allow equally spaced output samples (in time). By nature the filter calculates multiple output samples back-to-back after an input sample arrived. For output rates lower than the clock-speed, this leads to a bursting behavior which is often (but not always) undesirable. By controlling the *OutRdy* signal, the user can control the output sample-rate and –spacing exactly.

## PAUL SCHERRER INSTITUT

### 3.5.4 Architecture

The figure below shows the architecture of the CIC interpolation filter.

Note that the number format for the differentiator sections has one additional integer bit (compared to the input format) per section. This results from the fact that depending on the signal frequency, the differentiators can have a gain up to two.

If the gain correction multiplier is used, signal path is chosen to be 25 bits wide and the gain correction coefficient is 17 bits (unsigned). For most implementations this design decisions are sufficient. If other requirements exist (e.g. very wide signal path), a project specific implementation of the CIC is required.

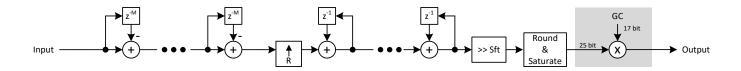

Figure 11: psi fix cic int fix 1ch Architecture

The symbols are defined as follows:

R Interpolation ratio

M Differential delay

N CIC order

Sft Number of bits to shift (to compensate overall gain to 0.5 < gain < 1.0)

GC Gain correction factor to compensate overall gain to 1.0

Some of the most common formulas are given below.

$$Gain_{CIC} = \frac{(R \cdot M)^{N}}{R}$$

$$Sft = ceil(\log_{2}(Gain_{CIC}))$$

For the case that the gain correction amplifier is disabled, the overall gain of the CIC is:

$$GainOverallNoGc = \frac{Gain_{CIC}}{2^{Sft}}$$

Since this formula evaluates to 1.0 for the case  $R = x^2$  (interpolation ratio is a power of two), the gain correction multiplier is not required in this case.

The optimal setting for the differential delay depends on the use case. Only the values 1 and 2 are supported. Other values are uncommon in real-life. Usually 1 is used if the input signal is already oversampled (does not contain frequency components close to  $\frac{fs}{2}$ ) and 2 is used otherwise.

Note that the CIC does not control timing on its own. This means by default, the CIC outputs one sample per clock cycle. If the input sample rate is slow, the output is bursting. If the time between two output samples has to be constant, the timing can be controlled by applying pulses at the desired frequency to the OutRdy handshaking signal. The reason for the CIC to not control any timing at the output is that this is a library component and it may also be used in offline processing algorithms.

# 3.6 psi\_fix\_cordic\_abs\_pl

## 3.6.1 Description

This component implements the absolute value calculation based on the CORDIC algorithm. Depending on the parameters, up to one pipeline stage per iteration can be implemented. This allows achieving even highest performance requirements.

Note that this component does not compensate the CORDIC gain. If this is required, the compensation of the CORDIC gain must be implemented externally.

#### 3.6.2 Generics

InFmt\_g Input format (must be signed)

Output format (must be unsigned since this is an absolute value)

InternalFmt\_g Number format used for all CORDIC calculations

**Iterations\_g** Number of CORDIC iterations to execute

PipelineFactor\_gA pipeline stage is implemented after every N iterations (1 = fully pipelined)

Round\_g Rounding mode at the output (round or truncate)
Sat g Saturation mode at the output (saturate of wrap)

#### 3.6.3 Interfaces

Signal	Direction	Width	Description

InQ	Input	InFmt_g	Quadrature-phase signal input		
Output					
OutVld	Output	1	AXI-S handshaking signal		
OutAbs	Output	OutFmt_g	Result output		

The CORDIC implementation is fully pipelined. This means it can take one input sample every clock cycle. As a result the handling of backpressure was not implemented.

## 3.6.4 Architecture

The CORDIC algorithm for the calculation of the absolute value is defined by the formulas below.

$$x_{i+1} = x_i - y_i \cdot d_i \cdot 2^{-i}$$
$$y_{i+1} = y_i + x_i \cdot d_i \cdot 2^{-i}$$
$$d_i = +1 \text{ if } y_i < 0, \text{else} - 1$$

The algorithm only works for  $x \ge 0$ , therefore the absolute value of x is calculated prior to executing the algorithm.

The CORDIC gain can be calculated by the formula below:

$$G_{CORDIC} = \prod_{i=0}^{N-1} \sqrt{1 + 2^{-2i}}$$

Where:

 $G_{CORDIC}$  Cordic Gain

N Number of iterations

The formula converges towards 1.646760 with high numbers of iterations.

The amount of Pipelining to be implemented can be chosen using the generic *PipelineFactor\_g*. However, the amount of logic (LUT) required does not change much with reduced pipelining. The main reason for reducing the amount of pipelining is latency reduction.

# 3.7 psi\_fix\_fir\_dec\_ser\_nch\_chpar\_conf

## 3.7.1 Description

This entity was initially implemented as multi-channel filter with configurable coefficients. However, it can also be used efficiently for single-channel FIRs and for filters with fixed coefficients.

This entity implements a multi-channel decimating FIR filter. All channels are processed in parallel (not TDM) but there is only one multiplier for each channel, so the taps of a channel are calculated one after the other. The filter coefficients, the order and the decimation rate are runtime configurable.

#### 3.7.2 Generics

InData	Input	$InFmt\_g \cdot Channels\_g$	Input data in parallel - Channel 0 [N-1:0] - Channel 1 [2*N-1:0]				
Output							
OutVld	Output	1	AXI-S handshaking signal				
OutAbs	Output	$OutFmt\_g \cdot Channels\_g$	Output data in parallel (see InData)				
Configuration							
Ratio	Input	ceil(log <sub>2</sub> (MaxRatio_g))	Decimation ratio -1 0 → no decimation 1 → decimation by 2)  This port is optional. If it is not connected,  MaxRatio_g is used as fixed ratio.				

# PAUL SCHERRER INSTITUT \_\_\_\_\_

Taps	Input	ceil(log <sub>2</sub> (MaxTaps_g))	<ul> <li>Taps – 1</li> <li>0 → 1 Tap (order 0 filter)</li> <li>63 → 64 Taps (order 63 filter)</li> <li>This port is optional. If it is not connected, MaxTaps_g is used as fixed tap count.</li> </ul>
Coefficient Int	erface		
CoefClk	Input	1	Clock for the coefficient interface.  This port can be left unconnected for fixed coefficient implementation ( <i>UseFixCoefs_g</i> = true)
CoefWr	Input	1	Coefficient write enable signal  This port can be left unconnected for fixed coefficient implementation ( <i>UseFixCoefs_g</i> = true)
CoefAddr	Input	ceil(log <sub>2</sub> (MaxTaps_g))	Address of the coefficient to access  This port can be left unconnected for fixed coefficient implementation ( <i>UseFixCoefs_g</i> = true)
CoefWrData	Input	CoefFmt_g	Coefficient value for write access ( <i>CoefWr</i> = 1)  This port can be left unconnected for fixed coefficient implementation ( <i>UseFixCoefs_g</i> = true)
CoefRdData	Output	CoefFmt_g	Coefficient read data (valid 1 cycle after applying the address)  This port can be left unconnected for fixed coefficient implementation ( <i>UseFixCoefs_g</i> = true)

The coefficient interface has a separate clock since often the data processing clock is coupled to an ADC clock but the main bus system that configures the filter is running on a different clock.

The filter can continue taking new input data even if a calculation is ongoing. As a result, the handling of packpressure is not required as long as the processing power of the filter is sufficient to handle all input data. For the calculation, see below.

Note that the behavior of the filter is undefined if the maximum input rate that can be handles is exceeded.

## PAUL SCHERRER INSTITUT

#### 3.7.4 Architecture

The figure below roughly shows the architecture of the FIR filter. Since the filter assumes all channels arrive in parallel with the same timing, the coefficient RAM is shared between all channels to save resources.

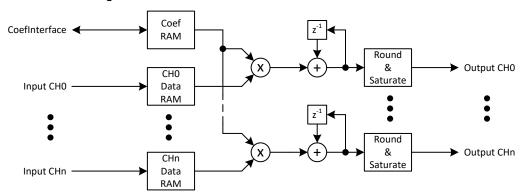

Figure 12: psi\_fix\_fix\_dec\_ser\_nch\_chpar\_conf Architecture

A state machine (not shown in the figure for simplicity) starts a new calculation whenever all required input samples for the next calculation arrived.

The accumulation is executed at the full output precision of the multiplication. This matches the implementation of the DSP slices in Xilinx devices, so they can be fully utilized.

The accumulator contains one guard bit compared to the output format to detect overflows. However, the user (designer who integrates the filter) is responsible to choose coefficients in a way that the output format is never exceeded by more than a factor of two. This this is not possible the filter output format must be chosen large enough ( $Range_{Output} \ge 0.5 \cdot MaximumOutput$ ) and saturated externally.

Obviously the architecture requires one clock cycle per tap calculation. As a result the maximum number of filter taps depends on the clock frequency  $F_{clk}$ , the input sample rate  $F_{s,in}$  and the decimation ratio R.

$$Taps_{max} = \frac{F_{clk} \cdot R}{F_{s.in}}$$

In case of fixed coefficient implementation, the coefficient RAM is replaced by a ROM automatically.

# 3.8 psi\_fix\_fir\_dec\_ser\_nch\_chtdm\_conf

## 3.8.1 Description

This entity was initially implemented as filter with configurable coefficients. However, it can also be used efficiently for filters with fixed coefficients.

This component implements a multi-channel decimating FIR filter. All channels are processed TDM (one after the other). The multiplications are all executed using the same multiplier, so the taps of a channel are calculated one after the other. The filter coefficients, the order and the decimation rate are runtime configurable.

The coefficient interface has a separate clock since often the data processing clock is coupled to an ADC clock but the main bus system that configures the filter is running on a different clock.

The filter can continue taking new input data even if a calculation is ongoing. As a result, the handling of packpressure is not required as long as the processing power of the filter is sufficient to handle all input data. For the calculation, see below.

Note that the behavior of the filter is undefined if the maximum input rate that can be handles is exceeded.

#### 3.8.4 Architecture

The figure below roughly shows the architecture of the FIR filter. Since the channels arrive one after the other, the one dual-port RAM is sufficient to store all data. The RAM is split into different regions (i.e. the higher address bits select the region reserved for a given channel).

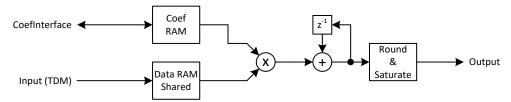

Figure 13: psi\_fix\_fix\_dec\_ser\_nch\_chtdm\_conf Architecture

A state machine (not shown in the figure for simplicity) starts a new calculation whenever all required input samples for the next calculation arrived.

The accumulation is executed at the full output precision of the multiplication. This matches the implementation of the DSP slices in Xilinx devices, so they can be fully utilized.

The accumulator contains one guard bit compared to the output format to detect overflows. However, the user (designer who integrates the filter) is responsible to choose coefficients in a way that the output format is never exceeded by more than a factor of two. This this is not possible the filter output format must be chosen large enough ( $Range_{Output} \ge 0.5 \cdot MaximumOutput$ ) and saturated externally.

Obviously the architecture requires one clock cycle per tap calculation of one channel. As a result the maximum number of filter taps depends on the number of channels  $N_{CH}$  clock frequency  $F_{clk}$ , the input sample rate  $F_{s.in}$  and the decimation ratio R.

$$Taps_{max} = \frac{F_{clk} \cdot R}{F_{s.in} \cdot N_{CH}}$$

In case of fixed coefficient implementation, the coefficient RAM is replaced by a ROM automatically.

**Important note**: Changing the decimation rate and/or the filter order at runtime can temporarily lead to inconsistent settings because usually they are changed by register accesses that are executed one after the other. To avoid this problem, it is suggested to keep the filter in reset whenever the parameters are changed.

# 3.9 psi\_fix\_lin\_approx\_<function>

## 3.9.1 Description

This is actually not just one component but a whole family of components. They are all function approximations based on a table containing the function values for regularly spaced points and linear approximation between them.

All components are based on the same implementation of the approximation (*psi\_fix\_lin\_approx\_calc.vhd*) and they only vary in number formats and coefficient tables.

The code is not written by hand but generated from Python (*psi\_fix\_lin\_approx.py*). If a new function approximation shall be developed, it can first be designed using the function *psi\_fix\_lin\_approx.Design()* that also helps finding the right settings. Afterwards VHDL code and a corresponding bittrueness testbench can be generated using *psi\_fix\_lin\_approx.GenerateEntity()* and *psi\_fix\_lin\_approx.GenerateTb()*.

#### 3.9.2 Generics

Since each function approximation is built for an exact input range, precision and function, no parameters are required.

#### 3.9.3 Interfaces

Signal	Direction	Width	Description	
Control Signals	Control Signals			
Clk	Input	1	Clock	
Rst	Input	1	Reset	
Input				
InVld	Input	1	AXI-S handshaking signal	
InData	Input	*	Signal input	
Output				
OutVld	Output	1	AXI-S handshaking signal	
OutData	Output	*	Result output	

<sup>\*</sup> The width of these ports depends on the specific function approximation.

The implementation of the linear approximation is fully pipelined. This means it can take one input sample every clock cycle. As a result the handling of backpressure was not implemented.

#### 3.9.4 Architecture

The figure below shows the interpolation principle.

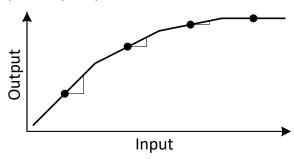

Figure 14: psi\_fix\_lin\_approx Interpolation Principle

The complete range of the function is split into small sections. For each section the center point as well as the gradient are known and the output value is calculated from these two values (together with the difference between actual input and center point of the current segment).

The figure below shows the implementation of the approximation.

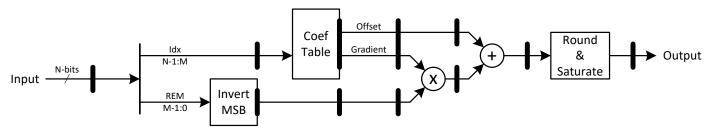

Figure 15: psi\_fix\_lin\_approx Architecture

After splitting the input into index and reminder, the reminder is unsigned and related to the beginning of the segment. By inverting the MSB, the reminder is converted to the signed offset related to the center point of the segment.

The addition after the multiplication is executed at full precision and without rounding/truncation. This allows for the adder being implemented within a DSP slice. The rounding/truncation is then implemented in a separate pipeline stage.

### 3.9.5 Function Details

#### 3.9.5.1 Sin18b

Function: Sine

**Input Range:** 0 ... 1 (in 2  $\pi$ )

Remarks: The sine wave is scaled down by exactly one LSB to exclude +/-1.0 to prevent an

additional integer bit being required for only this case.

### 3.9.5.2 Sqrt18b

Function: Square root Input Range: 0.25 ... 1

**Remarks:** If the input signal can be below 0.25, it must be shifted into this range and the shift must be

compensated at the output. This can be achieved by shifting the input by 2N bits to the left

and shift the output by N bits to the right since  $\sqrt{x} = \frac{1}{2^N} \sqrt{2^{2N}x}$ .

# 3.10 psi\_fix\_dds\_18b

## 3.10.1 Description

This entity implements an 18-bit DDS. The sine-wave is generated using the entity  $psi\_fix\_lin\_approx\_sin\_18b$  and it has an error of less than one LSB for all values. As a result, there are no significant spurs in the generated spectrum (significant in terms of above the quantization noise floor) as shown in the figure below.

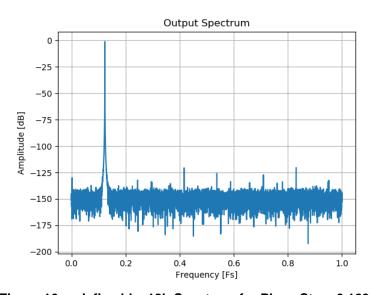

Figure 16: psi\_fix\_dds\_18b Spectrum for PhaseStep=0.12345

#### 3.10.2 Generics

**PhaseFmt\_g** Phase accumulator format. This must be a number format with a range of 1.0 (either [0,0,x] or [1,-1,x]). A phase of 1.0 corresponds to  $2\pi$  resp. one fully sine period.

#### 3.10.3 Interfaces

Signal	Direction	Width	Description
Control Signals			
Clk	Input	1	Clock
Rst	Input	1	Reset
Configuration			
Restart	Input	1	This signal can be used to start the DDS again at the phase offset. This is useful if 100% reproducible outputs must be generated several times.
PhaseStep	Input	PhaseFmt_g	Phase step between two consecutive output samples. The phase step is given in $2\pi$ (0.5 corresponds to $\pi$ ). The phase step can be changed at runtime safely.
PhaseOffset	Input	PhaseFmt_g	Phase offset of the generated signal. The phase offset is given in $2\pi$ (0.5 corresponds to $\pi$ ). The phase offset can be changed at runtime safely.

Input			
InVld	Input	1	AXI-S handshaking signal that can be used to generate samples at any rate. For continuous operation (one sample per clock cycle), the signal can be left unconnected.
Output			
OutVld	Output	1	AXI-S handshaking signal
OutSin	Output	18	Sine wave output in the format [1,0,17]
OutCos	Output	18	Cosine wave output in the format [1,0,17]

The total pipeline delay of the DDS is 10 clock cycles.

## 3.10.4 Architecture

The figure below shows the implementation of the DDS.

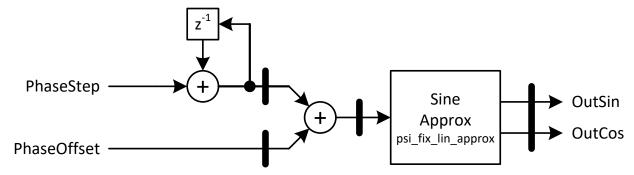

Figure 17: psi\_fix\_dds\_18b Architecture

# 3.11 psi\_fix\_lowpass\_iir\_order1

## 3.11.1 Description

This entity implements a first order IIR lowpass with integrated coefficient calculation.

Note that the filter is targeted mainly to applications where the cutoff frequency is only one or two orders of magnitude lower than the sampling frequency.

For cases where the cutoff frequency is close to DC, the requirements for coefficient precision grow with this straight-forward filter structure. In this case a completely different structure especially targeted to low cutoff frequencies should be used instead of this standard component.

The filter requires that the coefficient format is passed as generic. Therefore the coefficient calculations are given below, so the user can evaluate the coefficients and decide on a format with acceptable quantization error.

$$\alpha = e^{-2 \cdot \pi \cdot \frac{F_{cutoff}}{F_{sample}}}$$

$$\beta = 1 - alpha$$

#### 3.11.2 Generics

**FSampleHz\_g** Sample frequency in Hz (strobe frequency)

**FCutoffHz\_g** Cutoff frequency in Hz (-3dB point)

InFmt\_g Input format
OutFmt g Output format

IntFmt\_g
Format used for all internal calculations

CoefFmt g Coefficient format

**Round\_g** Rounding mode used everywhere in the filter (use *PsiFixTrunc* for highest clock speeds) **Sat\_g** Rounding mode used everywhere in the filter (use *PsiFixWrap* for highest clock speeds,

IIR filters of order 1 do not overshoot anyway, so saturation should not be required)

**Pipeline\_g** True → Highest clock frequencies but also higher latency

False → Lowest latency but reduced clock speed

**ResetPolarity g** Polarity of the reset ('1' = high active)

### 3.11.3 Interfaces

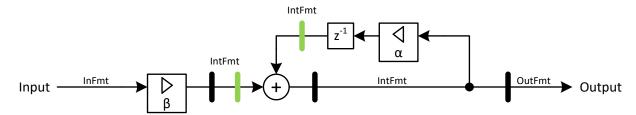

Figure 18: psi\_fix\_lowpass\_iir\_order1 Architecture

# 3.12 psi\_fix\_complex\_mult

## 3.12.1 Description

The block performs multiplication on a complex number pair (*Inphase* & *Quadrature*, inputs of the block) or 2D matrix computation, let two complex numbers be:

$$x = (a + ib); y = (c + id)$$

The multiplication result comes:

$$x.y = (a + ib)(c + id) = (ac - bd) + i(ad + bc)$$

Where: In-phase input=a; Quadrature input=b; I1=c; I2=d; Q1=I2=d; Q2=I1=c

The block could be seen as well as 2D matrix multiplication, apart from the fact that a subtraction is hardcoded on the in-phase path and the given processing is equal as the one shown below:

$$\begin{bmatrix} Iout \\ Qout \end{bmatrix} = \begin{bmatrix} Inphase \\ Quadrature \end{bmatrix} \times \begin{bmatrix} I1 & -I2 \\ Q1 & Q2 \end{bmatrix} = \begin{bmatrix} Inphase \times I1 - Quadrature \times I2 \\ Inphase \times Q1 + Quadrature \times Q2 \end{bmatrix}$$

The total pipeline delay of the block is 3 clock cycles if no pipeline activation is set through generics, otherwise the pipeline is doubled (i.e. 6 stages)

## 3.12.4 Architecture

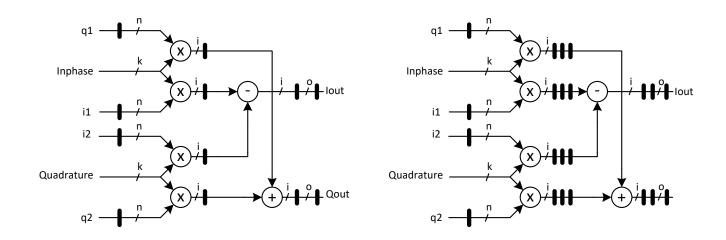

Figure 19: psi\_fix\_complex\_mult Architecture - Pipeline\_g = 0 (left) Pipeline\_g = 1

## 3.13 psi\_fix\_mov\_avg

### 3.13.1 Description

This entity implements a moving average implementation. It does not only calculate the moving sum but also compensate the gain from summing up multiple samples (either roughly by just shifting or exact by shifting and multiplication) if required.

The delay line is implemented using *psi\_common\_delay*, so the user can choose if SRLs or BRAMs shall be used or if the decision shall be taken automatically.

The gain of the filter including the compensation can be calculated by the formulas below:

$$G_{None} = Taps$$
  $G_{Rough} = rac{Taps}{2^{ceil(log2(Taps))}}$   $G_{Exact} = 1.0$ 

#### 3.13.2 Generics

InFmt\_g Input format OutFmt\_g Output format

Taps\_g Number of samples to do the moving average over

GainCorr\_g "NONE" The gain is not compensated

"ROUGH" The gain is roughly compensated by shifting (0.5 < gain < 1.0)

"EXACT" The gain is roughly compensated by shifting and then exactly adjusted using a

multiplier. The resulting gain is 1.0 (with the precision of the 17-bit coefficient).

Round\_g Rounding mode at the output
Sat\_g Saturation mode at the output
OutRegs\_g Number of output register stages

#### 3.13.4 Architecture

The figure below shows the implementation of the moving average filter. All three gain correction implementations are shown in the figure while only the selected one is implemented of course.

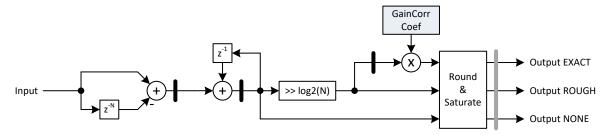

Figure 20: psi\_fix\_mov\_avg Architecture

The number formats are not shown in the figure for simplicity since there are some calculations required. For details about the number formats, refer to the code. All number formats are automatically chosen in a way that no overflows occur internally.

The output register is shown in grey since the number of output registers is configurable.

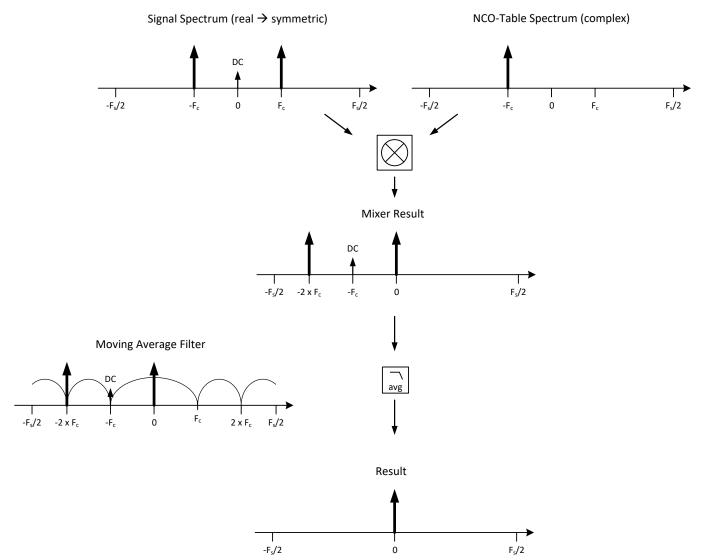

## 3.14 psi\_fix\_demod\_real2cplx

### 3.14.1 Description

This entity implements a simple demodulator that takes a real input and produces a complex result. The demodulator first mixes the signal with the carrier frequency (generated internally in the demodulator using a table) and then filters the output with a moving-average filter (comb-filter) with  $\frac{F_{sample}}{F_{carrier}}$  taps. This algorithm is illustrated in the figures at the end of this section.

The demodulator does only produce good quality results for very narrow-band signals with no significand outof-band noise. If the signal has significant sidebands or noise, either additional filtering after the demodulator is required or a specialized demodulator must be written.

Another requirement of the demodulator is, that the carrier frequency is an integer fraction of the clock frequency.

# PAUL SCHERRER INSTITUT \_\_\_\_\_

## 3.14.4 Architecture

The figure below shows the implementation of the demodulator.

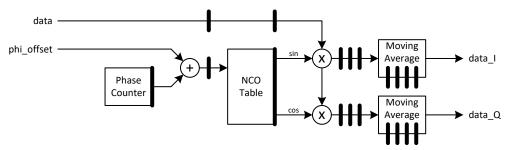

Figure 21: psi\_fix\_demod\_real2cplx Architecture

The additional pipeline stage for the phase counter does not have to be compensated because the phase counter is incremented only after each sample and not before.

## 3.15 psi\_fix\_cordic\_vect

### 3.15.1 Description

This entity implements the CORDIC algorithm for Cartesian to Polar conversion.

The CORDIC gain can optionally be compensated. If the gain is compensated externally, it is important to know the exact gain. Therefore the formula for calculating the CORDIC gain is given:

$$G_{CORDIC} = \prod_{i=0}^{Iterations-1} \sqrt{1 + 2^{-2*i}}$$

For the internal gain compensation it is recommended to choose an *InternalFmt\_g* in a way that it can be processed with one multiplier (e.g. for 7-series max. 25 bits).

#### 3.15.2 Generics

InFmt\_gOutFmt\_gInput format of the X/Y components (must be signed)Output format for the amplitude (must be unsigned)

**InternalFmt\_g** Internal calculation format for the X/Y components. (must be signed)

The more fractional bits, the more precise the calculation gets. Choose enough integer bits to ensure that no overflows happen.

For inputs in the form (1,0,x) that are always within the unit circle, (1,1,y) can be used. For inputs in the form (1,0,x) that can contain arbitrary values for X and Y, (1,2,y) can be

used.

AngleFmt\_g Angle output format (must be unsigned)

AngleIntFmt\_g Internal calculation format for angles (must be signed).

The more fractional bits, the more precise the calculation gets.

**Iterations q** Number of CORDIC iterations

GainComp\_g True The CORDIC gain (~1.62) is compensated internally with a multiplier

False The CORDIC gain is not compensated.

**Round\_g**Rounding mode at the output (use truncation for high clock speeds)
Sat\_g
Rounding mode at the output (use wrapping for high clock speeds)

Mode\_g "PIPELINED" One pipeline stage per CORDIC iteration, can take one sample every

clock cycle.

"SERIAL" One clock cycle per iteration, less logic utilitzation

#### 3.15.3 Interfaces

Signal	Direction	Width	Description	
Control Signals	5			
Clk	Input	1	Clock	
Rst	Input	1	Reset	
Input	Input			
InVld	Input	1	AXI-S handshaking signal	
InRdy	Input	1	AXI-S handshaking signal (only required for "SERIAL")	
Inl	Input	InFmt_g	Real part of the input signal	
InQ	Input	InFmt_g	Imaginary part of the input signal	
Output				
OutVld	Output	1	AXI-S handshaking signal	
OutAbs	Output	OutFmt_g	Absolute value of the output signal	
OutAng	Output	AngleFmt_g	Angle of the output signal (in $2\pi \rightarrow 0.5 = \pi = 180^{\circ}$ )	

#### 3.15.4 Architecture

The figure below shows the implementation of the vectoring CORDIC. The algorithm only works correctly in quadrant zero (where I and Q are positive). Therefore the input is mapped into this quadrant by sign swapping and the effect of this mapping is compensated at the output.

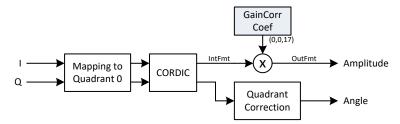

Figure 22: psi\_fix\_coric\_vect Architecture

## 3.16 psi\_fix\_cordic\_rot

### 3.16.1 Description

This entity implements the CORDIC algorithm for Polar to Cartesian conversion.

The CORDIC gain can optionally be compensated. If the gain is compensated externally, it is important to know the exact gain. Therefore the formula for calculating the CORDIC gain is given:

$$G_{CORDIC} = \prod_{i=0}^{Iterations-1} \sqrt{1+2^{-2*i}}$$

For the internal gain compensation it is recommended to choose an *InternalFmt\_g* in a way that it can be processed with one multiplier (e.g. for 7-series max. 25 bits).

#### Important Note:

In most cases (especially for Signals < 18 bits), the entity *psi\_fix\_pol2cart\_approx* (see 3.17) offers a better trade-off between resource usage and performance than the *psi\_fix\_cordic\_rot*. So it may be worth considering switching to that component.

#### 3.16.2 Generics

**InAbsFmt\_g** Format of the absolute (=amplitude) input (must be unsigned) Format of the angle input (must be unsigned), usually (1,0,x)

OutFmt\_g Output format for I/Q outputs, usually signed

InternalFmt\_g Internal calculation format for the X/Y components. (must be signed)

The more fractional bits, the more precise the calculation gets.

Choose enough integer bits to ensure that no overflows happen.

For inputs with an amplitude <= 1.0 (1.1 y) can be used.

For inputs with an amplitude <= 1.0, (1,1,y) can be used..

**AngleIntFmt\_g** Internal calculation format for angles (must be signed).

The more fractional bits, the more precise the calculation gets. The value is always < 0.25

(corresponds to 0.5  $^{*}$   $\pi$ ) since the calculation is always mapped into the same quadrant.

**Iterations\_g** Number of CORDIC iterations

**GainComp\_g** True The CORDIC gain (~1.62) is compensated internally with a multiplier

False The CORDIC gain is not compensated.

**Round\_g**Rounding mode at the output (use truncation for high clock speeds)
Sat\_g
Rounding mode at the output (use wrapping for high clock speeds)

Mode\_g "PIPELINED" One pipeline stage per CORDIC iteration, can take one sample every

clock cycle.

"SERIAL" One clock cycle per iteration, less logic utilitzation

#### 3.16.3 Interfaces

Signal	Direction	Width	Description	
Control Signals				
Clk	Input	1	Clock	
Rst	Input	1	Reset	
Input	Input			
InVld	Input	1	AXI-S handshaking signal	
InRdy	Input	1	AXI-S handshaking signal (only required for "SERIAL")	
InAbs	Input	InAbsFmt_g	Amplitude input	
InAng	Input	InAngleFmt_g	Angle input (in $2\pi \rightarrow 0.5 = \pi = 180^{\circ}$ )	
Output				
OutVld	Output	1	AXI-S handshaking signal	
Outl	Output	OutFmt_g	In-phase part of the output signal (X component)	
OutQ	Output	OutFmt _g	Quadrature-phase of the output signal (Y component)	

#### 3.16.4 Architecture

The figure below shows the implementation of the vectoring CORDIC. The algorithm only works correctly in quadrant zero (where I and Q are positive). Therefore the input is mapped into this quadrant by sign swapping and the effect of this mapping is compensated at the output.

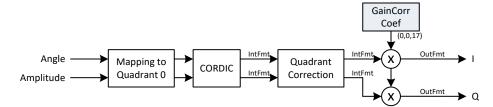

Figure 23: psi\_fix\_coric\_rot Architecture

## 3.17 psi\_fix\_pol2cart\_approx

## 3.17.1 Description

This entity implements a polar to cartesian conversion based on a linear approximation of the sine/cosine function. In most cases (especially for signals with less than 18 bits) this approach offers a better tradeoff between resource usage and performance.

Compared to the CORDIC implementation, 4 instead of 2 or 0 28x18 multipliers (depending on gain correction) are used and additional 72kBit of BRAM are used (= 4 RAMB18). On the other hand the LUT usage is lower than for the serial CORDIC implementation and the throughput is the same as for the pipelined CORDIC implementation.

#### 3.17.2 Generics

**InAbsFmt\_g** Format of the absolute (=amplitude) input (must be unsigned) Format of the angle input (must be unsigned), usually (1,0,x)

OutFmt\_g Output format for I/Q outputs, usually signed

**Round\_g**Rounding mode at the output (use truncation for high clock speeds)

Sat\_g

Rounding mode at the output (use wrapping for high clock speeds)

#### 3.17.3 Interfaces

Signal	Direction	Width	Description
Control Signals	3		
Clk	Input	1	Clock
Rst	Input	1	Reset
Input			
InVld	Input	1	AXI-S handshaking signal
InAbs	Input	InAbsFmt_g	Amplitude input
InAng	Input	InAngleFmt_g	Angle input (in $2\pi \rightarrow 0.5 = \pi = 180^{\circ}$ )
Output			
OutVld	Output	1	AXI-S handshaking signal
Outl	Output	OutFmt_g	In-phase part of the output signal (X component)
OutQ	Output	OutFmt _g	Quadrature-phase of the output signal (Y component)

### 3.17.4 Architecture

Note that some additional output registers outside the entity may be required if rounding and saturation are used.
